of the Requirements

for the Degree of

MASTER OF SCIENCE IN ENGINEERING

THE UNIVERSITY OF TEXAS AT AUSTIN

May 1980

A C K N O W L E D G M E N T S

To each of those who had a part in the completion of this thesis, I sincerely extend my gratitude: to Dr. James O. Jirsa for his friendship and for supervising this thesis; to Dr. John Breen for his friendship and for serving on my thesis committee; to Blake Stasney for his assistance in the fabrication and testing of the specimens; to Robin Longwell and Mike Lumsden for drafting the figures; to Maxine DeButts, Laurie Golding, George Moden, Gorham Hinckley, Dan Perez, Dick Marshall and Kyle Woodward for the technical skills they offered; and to Tina Robinson for typing this thesis.

I am especially indebted to Sam T. Burguières, Jr. for the countless hours he devoted to the planning of this project, to the fabrication and testing of the specimens, and to reduction of the data. But most of all, I thank him for his friendship.

The support of the National Science Foundation through Grants ENV75-00192 and ENV77-20816 for this work is gratefully acknowledged.

C H A P T E R 1

INTRODUCTION

1.1 Background

Recent earthquakes have stimulated an interest in the behavior of reinforced concrete structures subjected to seismic loadings. Of particular interest is the behavior of beam-column joints which must resist very high shear when lateral deformations are imposed on a moment-resisting frame (see Fig. 1.1). The strength and stiffness of the joints undergoing inelastic deformations will have a large influence on the overall frame performance.

Figure 1.2 shows the forces on a typical interior joint. The tensile forces produced by the longitudinal beam reinforcement plus the compressive forces on the opposite face of the joint must be resisted by either the concrete or the reinforcement in the joint. A better understanding of the mechanism of shear transfer across the joint is the key to improving the design of beam-column joints. In addition, the bond and anchorage behavior of the reinforcement, loss of cross-sectional area due to local spalling, and cracking of the joint region have an important influence on joint behavior.

Investigations in the past generally have been limited to beam-column joints of planar frames; however, researchers have recognized that two-way frames with lateral loads applied simultaneously in orthogonal directions may produce a more severe condition at the joint than has been observed in studies of planar joints.^{1,2,3,4} Hinging of orthogonal beams at the joint boundary will increase the resultant shearing forces on the joint and will

Fig. 1.1 Building frame subjected to lateral force⁶

Fig. 1.2 Equivalent member forces on an interior joint⁶

alter the cracking behavior of the joint region. Also, bidirectional loadings can produce higher moments on the columns than could occur under unidirectional loadings. Greater column moments combined with the decreased flexural strength of diagonally loaded rectangular columns is a potential problem that should be considered. Figure 1.3 shows the forces which occur on three faces at an interior joint when subjected to skewed lateral loads.

The design procedure for beam-column joints which is currently used in the United States was developed by the ACI-ASCE Committee 352. Beam-column joints with beams framing into the column from two principal directions are designed to resist joint shear in each direction independently and without regard to the

Fig. 1.3 Forces on joint subjected to bidirectional loads

influence of bidirectional loads. This shortcoming did not go unrecognized, and in the Committee 352 report, "the influence of biaxial forces on shear strength" was recommended as an area of needed research.⁵ A magnification of unidirectional design loads to account for the possibility of simultaneous loadings in both directions is an approach which may be suitable for design of beam-column joints. Selection of the proper magnification factor, however, is a problem which can only be resolved through experimentation. These needs led to the current investigation of the behavior of interior beam-column joints subjected to bidirectional load reversals.

1.2 Test Program

The fifth and sixth tests of a seven-test program are the subject of this study. To give the reader an overall view of the test program, a brief description of all of the specimens and their loadings is given. Each of the seven specimens had the same geometry as shown in Fig. 1.4. The reinforcement sizes and ratios and the type of loading for each specimen are given in Table 1.1. The specimens were named according to the test sequence, the type of loading, and the reinforcement details. For example, specimen 5-BS-A was tested fifth in the series, was loaded in both directions simultaneously (Biaxial Simultaneous), and had "A" reinforcement details. The "A" designates one of the four different reinforcement details (A, B, C, D) that were used (see Table 1.1). Other loading patterns which were used are Uniaxial (U), Biaxial Alternate (BA), and Monotonic Biaxial Simultaneous (MBS).

The reinforcement details of the first three specimens, 1-U-C, 2-BS-C, and 3-BA-C, were identical, but the load histories were different for each specimen. Specimen 1-U-C was loaded uniaxially and was the control specimen for the following two biaxial tests. Racking deformations were applied only to the

Fig. 1.4 Specimen geometry

North-South beams of specimen 1-U-C. Specimen 2-BS-C was loaded simultaneously in both the East-West (E-W) and North-South (N-S) directions simulating the racking loads which would occur if the lateral forces were skewed at a 45° angle with respect to the axes of the structure. Specimen 3-BA-C was also loaded biaxially, but deformations were applied alternately to the N-S and E-W beams. For example, the N-S beams were cycled once while the E-W beams were held at the dead load deflection, and then the E-W beams were cycled once while the N-S beams were held at the dead load deflection. Failure occurred in the joint of both specimens 1-U-C and 3-BA-C, but specimen 2-BS-C, which was simultaneously loaded in both directions had a column failure. Since column failure of the specimens was undesirable, a reevaluation of the design of the specimens for the remainder of the test program was necessary.

The percentage of beam-longitudinal reinforcement was reduced in the remaining four specimens to increase the strength of the column relative to the strength of the beams. The beam reinforcement of specimen 4-BS-B was reduced by $1/3$ to two #10's top and two #8's bottom. The bar diameters were kept the same as the previous specimens, so that a comparison of specimens 4-BS-A and 2-BS-C, which had similar bond behavior but different beam reinforcement ratios, could be made. The beam reinforcement of specimens 5-BS-A, 6-MBS-A, and 7-BS-D consisted of three #8's top and three #6's bottom. In those specimens, the beam reinforcement ratios were similar to the reinforcement ratios of specimen 4-BS-B, but the bar diameters were smaller. The effect of the bond characteristics of the smaller bars was an interesting aspect of these tests. Each of the last four specimens was loaded simultaneously in both directions and all the specimens were cyclically loaded except for specimen 6-MBS-A which was loaded monotonically. Future tests will explore the behavior of beam-column joints with slabs.

1.3 Scope and Objective

This study of reinforced concrete beam-column joints will be based on the test results of specimens 5-BS-A and 6-MBS-A. Both specimens had the same steel reinforcement details and were loaded in both principal directions simultaneously. The difference in the two tests was the applied load history. Specimen 6-MBS-A was loaded monotonically and specimen 5-BS-A was loaded cyclically. The primary objective is to compare the results of the two tests and to evaluate the performance of beam-column joints under the effects of racking moments applied to the joint in both directions. In addition, the measured joint shear strength of the specimens was compared with the calculated shear strengths obtained with design approaches based on previous studies of planar joints subjected to unidirectional loads.

C H A P T E R 2

SPECIMEN DESIGN

2.1 General

The beam-column joint specimens were specifically designed so that the joint core strength would be the controlling factor in specimen behavior. Also, the specimens were designed to have proportions typical of reinforced concrete framed structures. The column extended to mid-story height above and below the joint, based on the assumption that the mid-story height is a point of contraflexure in the column. The column and beam cross-sections were chosen to be 15 in. x 15 in. and 13 in. x 18 in., respectively, which were similar to the dimensions used by Meinheit and Jirsa in a previous study of planar joints at The University of Texas at Austin.⁶

2.2 Design Calculations

The design of the specimens was based on the following calculations. Assume:

$$f'_c = 4000 \text{ psi}$$

$$f_y = 60000 \text{ psi}$$

15 in. x 15 in. square column

13 in. wide x 18 in. deep beams

Design:

- (1) Joint core shear: Given a 15 in. x 15 in. column and 18 in. deep beams, the joint core shear strength formula developed by Meinheit and Jirsa was used to compute a joint core shear strength.

$$v_u = 5.1 \beta \zeta (f'_c)^{\frac{2}{3}}$$

where v_u = ultimate joint shear stress, psi

f'_c = concrete compressive strength, psi

β = $1 + 0.25w_L/h_c$ (influence of lateral beams)

w_L = width of the lateral beam perpendicular to the applied joint shear, in.

h_c = width of the column into which the lateral beam frames, in.

ζ = $1 + 6\rho_s \leq 1.6$ (influence of joint hoop reinforcement)

ρ_s = the volumetric percentage of transverse hoop reinforcement

$$\rho_s = \frac{A_h (2b^* + 2h^*)}{s_h b^* h^*}$$

A_h = area of the joint hoop bar (one bar area) in²

b^* = joint core dimension to outside of hoop, in.

h^* = joint core dimension to outside of hoop, in.

s_h = spacing of joint hoops, in.

Assuming #4 ties at 5 in. through joint core,

$$\rho_s = \frac{0.20 [2(12) + 2(12)]}{5(12)(12)}$$

$$= 0.0133$$

$$\zeta = 1 + 6(0.0133) = 1.08$$

$$\beta = 1 + 0.25(13/15) = 1.22$$

therefore,

$$\begin{aligned} v_u &= 5.1(1.22)(1.08)(4000)^{2/3} \\ &= 1690 \text{ psi} \end{aligned}$$

$$\begin{aligned} V_u &= \text{ultimate joint shear} \\ &= v_u b d \\ &= 1.69(15)(12.5) = 317 \text{ kips} \end{aligned}$$

- (2) Beam flexural reinforcement necessary to generate the above joint shear strength, V_u : using the relationship,

$$V_u = A_s^+ f_y + A_s^- f_y - V_{col}$$

where A_s^+ and A_s^- are the areas of positive and negative flexural reinforcement in the beams. Assuming $V_{col} \approx 40$ kips (see Fig. 2.1) and $A_s^+ \approx \frac{1}{2}A_s^-$, the areas of flexural reinforcement required can be determined as

$$317^k = A_s^-(60) + \frac{1}{2}A_s^-(60) - 40^k$$

$$A_s^- = 3.97 \text{ in}^2 \Rightarrow \text{use three \#10's top,}$$

$$A_s^- = 3.81 \text{ in}^2, \rho = 0.0189$$

$$A_s^+ = 1.98 \text{ in}^2 \Rightarrow \text{use three \#8's bottom,}$$

$$A_s^+ = 2.37 \text{ in}^2, \rho = 0.0117$$

- (3) Determine the maximum expected loads which will be applied to the specimen assuming the full yield moment of the beams is developed (refer to Fig. 2.1):

Fig. 2.1 Forces acting on specimen

$$\begin{aligned}
 M_y^- &= A_s f_y \left(d - \frac{a}{2}\right) \\
 &= 3(1.27)(60)(0.95)(15.5) \\
 &= 3370 \text{ in.-kips}
 \end{aligned}$$

$$V_{\max}^- = \frac{3370}{5(12)} = 56 \text{ kips}$$

$$\begin{aligned}
 M_y^+ &= A_s f_y \left(d - \frac{a}{2}\right) \\
 &= 3(0.79)(60)(0.95)(15.5) \\
 &= 2090 \text{ in.-kips}
 \end{aligned}$$

$$V_{\max}^+ = \frac{2090}{5(12)} = 35 \text{ kips}$$

$$\begin{aligned}
 M_{\text{col}} &= \frac{M_y^- + M_y^+}{2} && \text{(Assuming equal distribution} \\
 &= \frac{3370 + 2090}{2} && \text{of total beam moment to} \\
 &= 2730 \text{ in.-kips} && \text{column above and below.)}
 \end{aligned}$$

- (4) Determine longitudinal column reinforcement required to resist column moment developed. Consider the column as a simple flexural member with one layer of reinforcement:

$$\begin{aligned}
 (A_s)_{\text{required}} &= \frac{M_{\text{col}}}{f_y \left(d - \frac{a}{2}\right)} = \frac{2730}{60(0.95)(12.5)} \\
 &= 3.83 \text{ in}^2
 \end{aligned}$$

Therefore, use four #9's; $A_s = 4.00 \text{ in}^2$. The above calculations indicate the need for twelve #9 longitudinal reinforcing bars in the column giving an effective four bars per face for flexure.

$$\rho_{\text{col}} = \frac{12(1.00)}{15(15)} = 0.0533$$

- (5) Check shear capacity of column above and below the joint:
 assume $V_{col\ max} = 50^k$ due to possible unequal distribution
 of column shears, $P = 0$, and $V_c = 0$ (shear carried by
 concrete).

$$V_s = \frac{V_{col\ max}}{\phi} = \frac{50}{0.85}$$

$$= 59\ \text{kips}$$

Assume #4 ties; $A_s = 0.20\ \text{in}^2$

$$s = \frac{A_v f_y d}{V_s} = \frac{0.40 (60) 12.5}{59}$$

$$= 5.1\ \text{in.}$$

To be conservative, use #4 ties at 4 in.

- (6) Check shear capacity of beams: assume $V_{max} = 60^k$ and #3
 stirrups; $A_s = 0.11\ \text{in}^2$

$$V_n = \frac{V_{max}}{\phi} = \frac{60}{0.85}$$

$$= 70.6\ \text{kips}$$

$$V_c = 2\sqrt{f'_c} bd = 2\sqrt{4000} (13)(15.5)$$

$$= 25,500\ \text{lbs.}$$

$$V_s = V_n - V_c = 70.6 - 25.5$$

$$= 45.1\ \text{kips}$$

$$s = \frac{A_v f_y d}{V_s} = \frac{0.22 (60) (15.5)}{45.1}$$

$$= 4.5\ \text{in.}$$

Use #3 stirrups at 4 in.

After testing the first three specimens, it was apparent that biaxial loadings on the column together with a deterioration of the bond of the column reinforcement produced greater distress in the column than had been anticipated. Therefore, the amount of beam longitudinal reinforcement was reduced in subsequent specimens to increase the relative strength of the column. The design of specimens 5-BS-A and 6-MBS-A was the same as the first three except that the beam reinforcement consisted of three #8's top and three #6's bottom.

2.3 Specimen Details

The details of both specimens 5-BS-A and 6-MBS-A were identical. The beams were 13 in. x 18 in. with $1\frac{1}{2}$ in. cover and had #3 stirrups at a 4 in. spacing (see Fig. 2.2). Top and bottom longitudinal reinforcement consisted of three #8 bars and three #6 bars, respectively and was continuous through the joint. Crossing of the beams at the joint required the placement of the E-W longitudinal reinforcement below the N-S longitudinal reinforcement as shown in Fig. 2.3. This slightly increased the positive moment capacity and decreased the negative moment capacity of the E-W beams compared to the N-S beams. Moment-curvature diagrams for both positive and negative bending of the beams are shown in Fig. 2.4.

The column had a 15 in. x 15 in. square cross section with twelve equally spaced #9 bars as shown in Fig. 2.5. Transverse reinforcement consisted of #4 ties at a 4 in. spacing with $1\frac{1}{2}$ in. cover. At the joint, the tie spacing was increased to 5 in., with two ties within the joint core. Figure 2.6 is an interaction diagram for the column cross section and has curves for both uniaxial and 45° biaxial loading. In either case, the moment capacity shown is the component for each principal direction. The diagram shows that the balanced condition occurs at 300 kips which

Fig. 2.2 Specimen details

Fig. 2.3 Beam cage

Fig. 2.4 Moment-curvature diagram for beams

Fig. 2.5 Column cross section

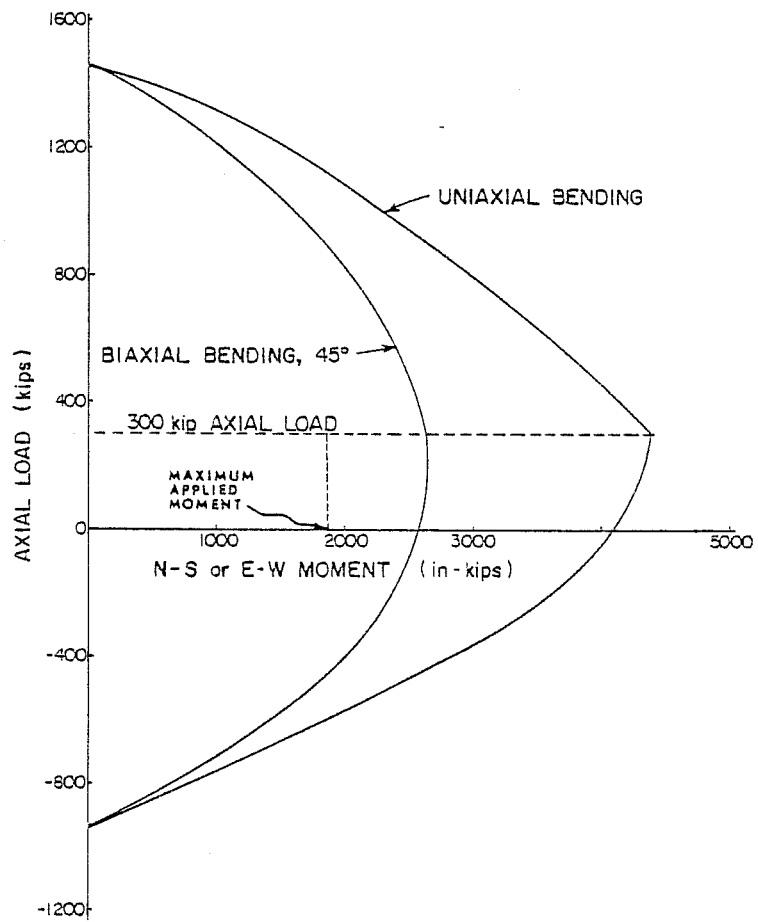

Fig. 2.6 Column interaction diagram

is the axial load that was applied to the specimens. Figure 2.7 shows combinations of the N-S and E-W components of moment capacity at a 300-kip axial load. The resultant moment capacity of the column loaded on a 45° angle is approximately 90 percent of the "uniaxial" strength.

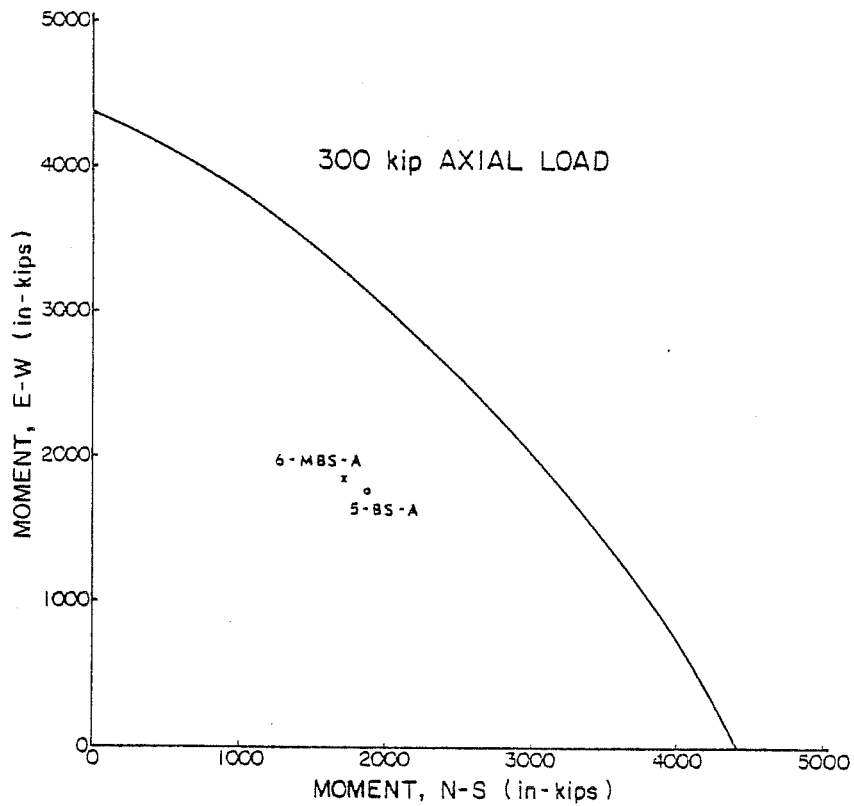

Fig. 2.7 Interaction of N-S and E-W moment capacities of column

C H A P T E R 3

EXPERIMENTAL STUDY

3.1 Specimen Fabrication

Fabrication of each specimen consisted of tying the beam and column cages, placing the cages in the forms, securing the instrumentation reference inserts, placing the concrete, and curing the specimen.

First, the column bars and the lower column hoops were tied together to form the column cage which was placed in the form with four 1 in. diameter column base anchor bolts in position (see Fig. 3.1). Next, the lower column forms were lightly oiled and bolted in place securing the column cage in its final position. The beam cages and the two joint core ties were simultaneously lowered over the column bars as shown in Fig. 3.2. With the beam cages resting on the surface of the platform (see Figs. 3.3 and 3.4) the rest of the forms were bolted in place.

In order to provide fixed references from which to measure joint shear strain, joint rotation, beam rotation, and bar slip, steel inserts were secured at various locations in the joint region (see Fig. 3.5). All the inserts were insulated from the cover concrete by pieces of foam rubber taped to the inserts. This method was adopted to prevent erroneous measurements due to spalling of the cover concrete.

Each specimen was cast in two stages. The first cast included the lower column, the beams, and the joint region. After casting, the specimen was covered with a plastic sheet and cured for several days before the forms were removed. The specimen was

Fig. 3.2 Placement of beam cages

Fig. 3.3 Final position of beam and column cages

Fig. 3.4 Joint region reinforcement

Fig. 3.5 Instrumentation reference inserts
mounted to formwork

then moved to a rack where the upper column hoops were positioned and tied (see Fig. 3.6). The upper column anchor bolts were also positioned and tied before the upper column forms were bolted in place (see Fig. 3.7). The specimen was then ready for casting of the upper column. After casting, the specimen was again covered with a plastic sheet and cured for several days before removing the forms. The concrete mix proportions given in Table 3.1 were used for all specimens.

3.2 Material Properties

Concrete cylinders (6 in. x 12 in.) were cast with each batch of concrete and were cured in the same manner as the specimen. Average cylinder strengths for the specimens are given in Table 3.2. Since the concrete strengths of the joint region (first cast) were fairly close for the two specimens, comparisons of the tests were possible without normalizing concrete strength.

Steel reinforcement for the two specimens consisted of #3 beam stirrups, #4 column ties, #6 bottom beam bars, #8 top beam bars, and #9 column bars. The same lot of steel for each bar diameter was used for both the monotonically and cyclically loaded specimens. Several coupon tests were conducted for each bar diameter using a 600-kip Universal Testing Machine. Stress and strain measurements were taken electronically and plotted with an x-y recorder as shown in Fig. 3.8. The steel reinforcement properties are summarized in Table 3.3.

3.3 Testing Apparatus

The testing apparatus shown in Fig. 3.9 consisted of an upper and lower loading head, two column shear struts, and a reaction wall. Both the upper and lower loading heads were grouted and bolted to the column. The lower loading head was bolted to the floor as well, while the top loading head was pin connected to two shear struts.

- A upper loading head
- B shear strut
- C axial rod
- D beam ram
- E lower loading head

Fig. 3.9 Testing apparatus

The other ends of the shear struts were pin connected to the reaction wall.

Four axial rod assemblies were used to apply the axial load to the column. Each rod was positioned with the upper and lower loading heads between two bearing plates of the axial rod assembly. Four hydraulic rams at the top of the axial rod assemblies were connected with hydraulic hoses to a manifold which maintained equal pressure in the four rams. A floor pump provided hydraulic pressure to the manifold where it was distributed to the rams. As the rams extended, tensile stresses in the rods and compressive stresses in the column were produced.

Beam loads were applied with double-rodded hydraulic rams. Two independent hydraulic systems which are illustrated in Fig. 3.10 were used for loading the N-S and the E-W beam systems. To simulate dead load, both beams were displaced downward by an equal amount. Oil was pumped through the right pump manifold and into the top of the two rams, forcing the beams down. Simultaneously, oil was forced from the bottom of the rams and back to the pump through the left manifold. This is a closed hydraulic system, and ideally, the amount of oil in the system remains constant.

In addition to applying dead load, the hydraulic system was used to apply the racking load to the specimens. After the dead load was applied, the south (east) beam was displaced upward. Hydraulic oil was pumped through the right manifold to the bottom of the south (east) beam ram forcing the beam up. At the same time, oil was forced out of the top of the south (east) beam ram and into the top of the north (west) beam ram forcing the north (west) beam down by an equal amount. Oil then returned to the pump from the bottom of the north (west) beam ram. To reverse the load, pressure was released with valve 2, and then oil was pumped in the opposite direction.

Fig. 3.10 Beam hydraulic loading system

3.4 Specimen Instrumentation

3.4.1 Joint Shear Strain. Joint shear strain was measured with the device shown in Figs. 3.11(a) and (b). A potentiometer was mounted on a sliding arm of the triangle formed by the extensions of the rods connected to three pins embedded in the joint core. The potentiometer was used to measure the change in length of the side of the triangle as changes in joint shear strain occurred. Having this measurement, the law of cosines was used to calculate joint shear strain (see Fig. 3.12).

3.4.2 Joint Rotation. Joint rotation was measured using two potentiometers mounted to a stationary frame independent of the specimen (see Fig. 3.13). Two plates were connected to bolts embedded in the column above and below the joint providing a reference from which to measure joint rotation. Figure 3.14 is an exaggerated illustration of the deformation of the specimen which shows the joint rotation geometry. The calculation of the joint rotation which follows refers to this figure.

JR = joint rotation, rad.

h_j = height of joint, in.

x = difference in potentiometer readings, in.

a = distance of potentiometer above and below beam, in.

L_c = distance from joint to point of inflection, in.

θ_f = elastic flexural rotation of column, rad. (see Fig. 4.20)

$x_1 = a(JR + \theta_1 - \theta_f)$

$x_2 = a(JR + \theta_2 - \theta_f)$

(b)

(a)

Fig. 3.11 Shear strain instrumentation

(a) Schematic of joint shear strain instrumentation

(b) Joint shear strain geometry

α = joint shear strain, radians

Δ_a = potentiometer measurement, in.

Law of cosines:

$$a^2 = b^2 + c^2 - 2bc \cos \angle A$$

$$\angle A = \cos^{-1} \left(\frac{b^2 + c^2 - a^2}{2bc} \right)$$

$$= \cos^{-1} \left(\frac{b^2 + c^2 - (\sqrt{b^2 + c^2} + \Delta a)^2}{2bc} \right)$$

$$= \cos^{-1} \left(\frac{128 - (11.31 + \Delta a)^2}{128} \right)$$

$$\alpha = \pi/2 - \angle A$$

Fig. 3.12 Joint shear strain calculation

Fig. 3.13 Joint rotation instrumentation

Fig. 3.14 Joint rotation geometry

By geometry,

$$\begin{aligned}
 m + n &= JR(h_j) \\
 \theta_1 L_c + \theta_2 L_c &= JR(h_j) \\
 \theta_1 + \theta_2 &= \frac{h_j}{L_c} JR \\
 JR &= \frac{x + x_1 + x_2}{h_j + 2a} \\
 &= \frac{x}{h_j + 2a} + \frac{2JR(a) + a(\theta_1 + \theta_2) - 2\theta_f(a)}{h_j + 2a} \\
 &= \frac{x}{h_j + 2a} + \frac{JR(a)}{h_j + 2a} \left(2 + \frac{h_j}{L_c} \right) - \frac{2\theta_f(a)}{(h_j + 2a)}
 \end{aligned}$$

For this geometry, $a = 4$ in. $h_j = 18$ in., $L_c = 63$ in.

$$JR = 0.0593x + 0.475\theta_f$$

3.4.3 Beam Rotation. Rotations of the south and east beams were measured with potentiometers in a similar manner as joint rotation, except that the potentiometers were mounted on a bracket which was attached to the beam (see Fig. 3.15). The bracket was attached to the beam at 7 in. from the face of the column, so that the measurement included both elastic and inelastic beam rotation concentrated within the 7 in. length. Figure 3.16 shows the deformation geometry for the calculation of beam rotation which follows.

BR = beam rotation, radians

y = difference in potentiometer readings

b = distance of potentiometers above and below beam

Fig. 3.15 Beam rotation instrumentation

Fig. 3.16 Beam rotation geometry

$$\begin{aligned}
 y_1 &= b(JR + \theta_1 - \theta_f) \\
 y_2 &= b(JR + \theta_2 - \theta_f) \\
 BR &= \frac{y - (y_1 + y_2)}{h_j + 2b} \\
 &= \frac{y}{h_j + 2b} - \frac{2JR(b) + b(\theta_1 + \theta_2) - 2\theta_f(b)}{h_j + 2b}
 \end{aligned}$$

From joint rotation calculation, recall that:

$$\begin{aligned}
 \theta_1 + \theta_2 &= \frac{h_j}{L_c} JR \\
 BR &= \frac{y}{h_j + 2b} - b \left(\frac{2JR + \frac{h_j}{L_c} (JR) - 2\theta_f}{h_j + 2b} \right)
 \end{aligned}$$

For this geometry, $b = 3\frac{1}{2}$ in., $h_j = 18$ in., $L_c = 63$ in.

$$BR = 0.040y - 0.320JR + 0.280\theta_f$$

3.4.4 Beam Deflection. Beam deflections were measured with twelve-inch potentiometers mounted to the beam rams as shown in Fig. 3.17. The slide rod of the potentiometer was connected to the piston of the ram so that when the ram extended, the rod extended the same amount.

3.4.5 Loads. Beam loads, axial column load, and column shear were all measured electronically with load cells. Beam loads were measured with load cells connected between the beam rams and the beam ends. To measure column axial load, four strain gages were mounted on two of the axial rods and connected to form a Wheatstone bridge. The rods were then calibrated prior to testing

Fig. 3.17 Beam deflection instrumentation

of the specimens. Column shear was measured in the same manner with full bridge circuitry mounted on each of the two shear struts connecting the upper loading head and the reaction wall.

3.4.6 Reinforcing Bars. Electrical resistance strain gages were mounted on beam, column, and joint hoop reinforcement. Strain gages for the beam and column bars were located at the beam-column boundaries (see Fig. 3.18). In addition, selected bars had strain gages at 8 in. and 16 in. from the critical section, and joint hoops had gages on each of the four sides of the hoop. Paper gages with 0.64 in. gage length were used throughout. Figure 3.19 shows several bars with mounted gages and waterproof protection.

In addition to strain, slip of the longitudinal beam reinforcement was measured at the joint boundaries. This was done with a piece of piano wire attached to the bar at the critical section and extended through the joint and out the face of the column as illustrated in Fig. 3.20. The slipwire was attached to the reinforcing bar by inserting the wire with a 90° bend into a hole drilled in the bar and using a plastic tie to secure the connection (see Fig. 3.21). In addition, plastic tubing was used to provide a passage for the slip wire. As shown in Fig. 3.22, a potentiometer was mounted on a bolt connected to a reference insert embedded in the column. Both the slipwire and the plunger of the potentiometer were spring loaded to provide continuous contact as movement of the slipwire occurred.

Column and joint rotations introduced an error in the slip measurements which required a correction. Correction of individual bar slips depended on both instrument location and on the division of column rotation above and below the joint. It was assumed that the column rotation was split evenly. Figure 3.23 shows the geometry of the joint region with regard to bar slip and the correction is calculated as follows:

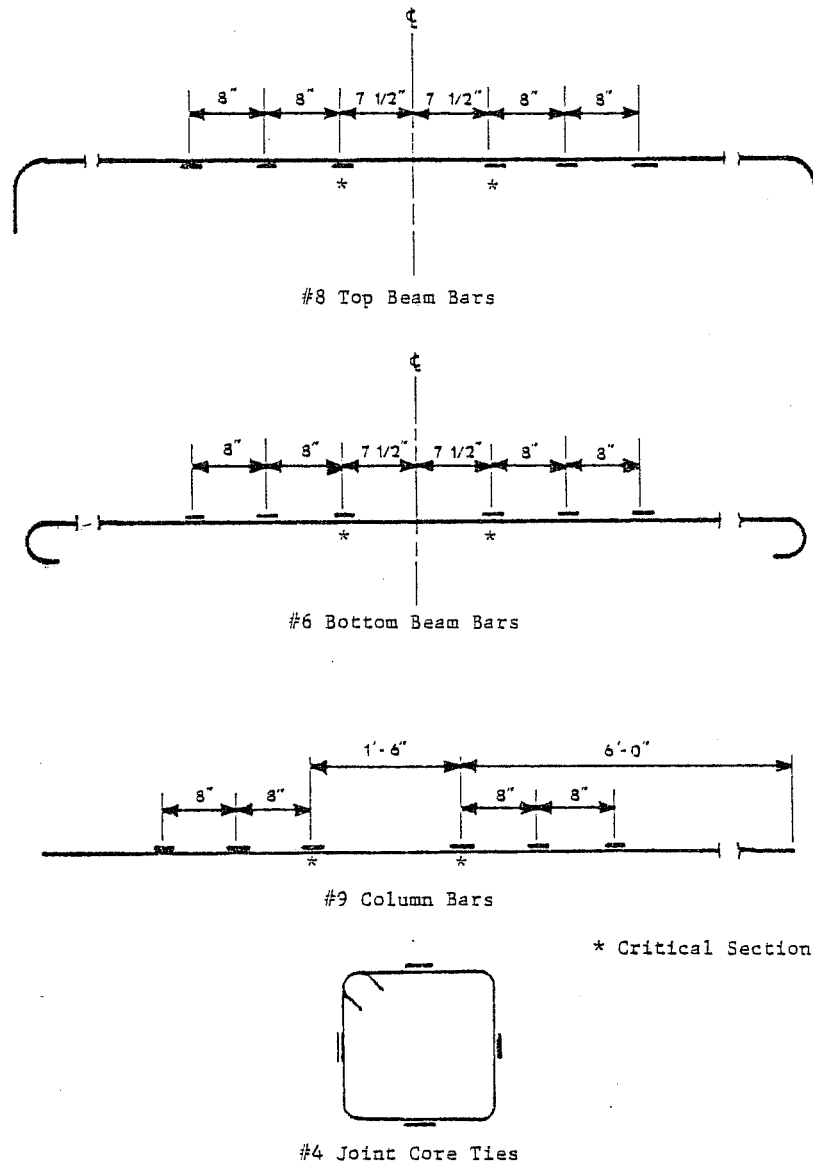

Fig. 3.18 Strain gage locations

Fig. 3.19 Mounted strain gages

Fig. 3.20 Bar slip instrumentation

Fig. 3.21 Slip wire connection (see arrow)

Fig. 3.22 Bar slip measuring device

Fig. 3.23 Bar slip geometry

- SL_c = corrected bar slip
 SL = measured bar slip
 z = distance from face of joint to ξ of bar
 x = amount of correction
 θ_1 = column rotation above (see Fig. 3.14)
 θ_2 = column rotation below (see Fig. 3.14)
 θ_f = elastic column rotation (see Fig. 4.20)
 JR = joint rotation
 θ = total column rotation (above or below)

Assuming an even split of column rotation above and below,

$$\theta = \frac{\theta_1 + \theta_2}{2} - \theta_f$$

From joint rotation calculation, recall that:

$$\theta_1 + \theta_2 = \frac{h_j}{L_c} JR$$

$$\theta = \frac{h_j}{2L_c} JR - \theta_f$$

$$\psi = \theta + JR$$

$$= \left(1 + \frac{h_j}{2L_c}\right) JR - \theta_f$$

$$x = \psi z$$

and

$$SL_c = SL - x$$

3.5 Test Procedure

Each specimen was pretested prior to the day of the full test. The specimens were subjected to one elastic cycle during the pretest, the purpose of which was to check the operation of the hydraulic and electrical systems. The maximum beam deflection at the peak of the elastic cycle was 0.3 in.

To start the main test, a data reading was taken with the specimen under zero load. The first reading is referred to as the zero reading and is the base from which all other readings are referenced. Next, a 300-kip axial load was applied to the column and another reading was taken. Readings were also taken after the N-S and E-W beam dead load deflections were imposed. Racking loads were then applied simultaneously to the N-S and E-W beams in increments, and data readings were taken at each increment. Loading of the beams was controlled with valves on the hydraulic consoles while the level of deflection of the north and west beams was continuously monitored with x-y recorders (see Fig. 3.24). A complete description of the applied load histories is given in Chapter 4.

3.6 Data Acquisition and Reduction

Data were taken electronically with a digital data acquisition system in conjunction with a mini-computer. On line data reduction enabled teletype monitoring of selected channels as the test progressed. The test data were stored on a computer disk and were later run through a data reduction program which converted the voltage readings into engineering units. Plot files of the channels were then created, and plots of selected channels were made. A digital plotter was a valuable tool which permitted the user to make plots of desired size and scale and to put titles on the plots.

Fig. 3.24 Testing controls

C H A P T E R 4

TEST RESULTS AND BEHAVIOR

4.1 General

In this chapter, the test results of specimens 5-BS-A and 6-MBS-A are presented. Both specimens were subjected to deformation controlled racking loads at a 45° angle to the principal axes of the subassembly. The loading pattern was chosen to simulate seismic loadings which are produced at the beam-column joints of reinforced concrete frames when the ground motion is skewed to the principal axes of the structure. The difference in the two tests was that specimen 6-MBS-A was monotonically loaded, and specimen 5-BS-A was cyclically loaded. Comparisons of the test results will show the effects of cycling of deformations on joint performance.

The deformation levels which the specimens were subjected to are denoted by multiples of Δ_1 ($1\Delta_1$, $2\Delta_1$, etc.) which was determined to be the yield deflection of the beams in specimen 1-U-C and was established as the nominal yield deflection for all the specimens. Specimens 5-BS-A and 6-MBS-A, however, had smaller diameter beam reinforcement than specimen 1-U-C. Consequently, the bond characteristics were better for specimens 5-BS-A and 6-MBS-A, and the beams reached yield at a lower deflection than 1-U-C. To maintain uniformity in the testing program, all the specimens were subjected to the same levels of deformation. For the two tests referred to in this chapter, the Δ_1 designation is only a reference deflection and does not correlate directly with yield of the specimens.

4.2 Monotonic Test, 6-MBS-A

4.2.1 Description of Load History. The column of the monotonically loaded specimen was axially loaded with approximately 300 kips which was maintained throughout the test. After applying the axial load, a dead load deflection of 1/10 in. was imposed on each of the four beams. Next, the deflections producing racking were applied to the beams (see Fig. 4.1). The north and west beams were deflected downward (+), while the south and east beams were simultaneously deflected upward (-) by the same amount. The specimen was loaded in this direction until the loading ram reached maximum extension of 5 in. Although this concluded the monotonic test, the specimen was then cycled at the $3\Delta_i$ deformation level.

4.2.2 Load-Deflection Behavior. Plots of beam load versus beam end deflection in Figs. 4.2 and 4.3 show that the beam ultimate loads were very close to the calculated ultimate loads and remained essentially constant as the beams were deflected to the limit of the loading apparatus. This indicates that any strength degradation of the specimen subjected to cyclic loads is due to load reversal and cycling rather than a decrease in the capacity of the joint at high deformations. The cycles subsequent to the monotonic loading show a large reduction in strength and stiffness. Near the neutral position, deflections of the beams were accompanied by only slight changes in load. The low stiffness could be due to a combination of both beam and column bar slip and shearing of the joint region, and the loss of strength may be due to degradation of concrete strength and loss of cross-sectional area due to spalling of cover concrete.

4.2.3 Cracking Patterns. Joint shear cracks were first visible at the northeast and southwest corners of the joint at load stage 9 as shown in Fig. 4.4. At this stage, the north and south beam deflections were +0.52 and -0.43 in., respectively. In

Fig. 4.1 Specimen 6-MBS-A load history

Fig. 4.2 Load deflection behavior, 6-MBS-A (north beam)

Fig. 4.3 Load deflection behavior, 6-MBS-A (south beam)

Fig. 4.4 First shear cracks, 6-MBS-A

addition to joint shear cracks, flexural and flexural-shear cracks in the beams were also visible. At load stage 15, the north and south beam deflections were 1.12 and -0.92 in., respectively, and first yielding of the beam reinforcement was evident as the beam loads increased very little as higher deformations were imposed. Figure 4.5 shows that joint shear cracking extended well into the beams at this stage. At the $1\Delta_1$ deformation, considerable cracking of the joint region had occurred and in Fig. 4.6, the diagonal shear cracks of the southwest corner of the joint are shown. Figure 4.7 shows that at $2\Delta_1$ deformation, crushing of the cover concrete had occurred in the compressive zone of the lower column. In addition, splitting cracks were observed on the top of the north and west beams. The north beam, which had an inch less top cover concrete than the west beam, had more splitting along the longitudinal beam bars (see Fig. 4.8). At peak deformation under monotonic loading, extensive joint shear cracking was visible as shown in Fig. 4.9. Joint shear cracking extended into the compression zone of the north beam fracturing the corner of the beam cross section. Also, the compression zone of the lower column showed considerable distress.

4.3 Cyclic Test, 5-BS-A

4.3.1 Description of Load History. The cyclically loaded specimen was initially subjected to a 300-kip axial load and 1/10 in. beam dead load deflections (same as the monotonic test). Then racking loads were applied as shown in Fig. 4.10. The north and west beams were deflected downward (+) while the south and east beams were simultaneously deflected upward (-) by the same amount. The beams were loaded to a deflection of $1\Delta_1$ and then cyclic loading was applied. The same loading procedure was used for the $2\Delta_1$ and $3\Delta_1$ deformation levels with three cycles at each level.

Fig. 4.5 Shear cracking at first yield, 6-MBS-A

Fig. 4.6 Shear cracking at $1\Delta_1$, 6-MBS-A

Fig. 4.8 Splitting cracks at $2\Delta_1$, 6-MBS-A

Fig. 4.9 Shear cracking at peak deformation, 6-MBS-A

Fig. 4.10 Specimen 5-BS-A load history

4.3.2 Load-Deflection Behavior. The beam load versus beam end deflection plots (see Figs. 4.11 and 4.12) show that the stiffness degrades substantially during the first cycle at a deformation level. This indicates that most of the damage to the joint occurs during the initial excursion to a higher deformation. There was some further degradation of stiffness during the second and third cycles as well. Except for the initial loading at a given deformation, the load-deflection behavior was characterized by severe pinching of the hysteresis loops. This behavior indicates that joint shear distortion and/or reinforcing bar slip was a major influence on the performance of the joint.

Although there was a large degradation of stiffness after cycling at $1\Delta_1$, the beam loads reached calculated ultimate load when the beams were deformed to $2\Delta_1$. At $3\Delta_1$, however, strength degradation was evident as the beam loads were well below the calculated strengths. The initial direction of loading influenced the strength when the load was reversed. The beam loads were always less than the calculated strength at the second peak of the first cycle at any given deformation. This may be due to degradation of bond of the tensile reinforcement during the initial excursion, so that the reinforcement was not effective in compression when the load was reversed. Also, degradation of the bond through the joint will cause tensile stresses to be produced in the reinforcement in the compressive zones of the beams. The result will be higher compressive stresses in the concrete and will lead to faster deterioration of the beam (see Fig. 4.13). Similar behavior can occur in the column as well.

4.3.3 Cracking Patterns. The cracking patterns of the cyclically loaded specimen were similar to the monotonically loaded specimen up to the first peak at $1\Delta_1$ deformation. The load histories for the two specimens were the same at this stage. After

Fig. 4.11 Load deflection behavior, 5-BS-A (north beam).

Fig. 4.12 Load deflection behavior, 5-BS-A (south beam)

a) Force Equilibrium Required by Strain Compatibility

b) Force Equilibrium Because of Shear and Bond Failure

Fig. 4.13 Force equilibrium of joint failing by shear and bond⁶

reversing the load, crossing of the joint shear cracks was observed in the northeast and southwest corners of the joint. The joint shear cracks are visible where the north and east beams frame into the column as shown in Fig. 4.14. An overall view of the cracking patterns is shown in Fig. 4.15. In addition, splitting cracks were observed on top of the north and south beams. Few splitting cracks were observed on the top of the east and west beams since the top cover concrete was greater for those beams. However, splitting cracks were observed on the sides of the east and west beams. After cycling three times at $1\Delta_1$, very few new cracks appeared, but extensions of existing cracks were observed. Figure 4.16 shows a general view of the specimen after three cycles at $1\Delta_1$.

Fig. 4.14 Joint shear cracking at second peak, $1\Delta_1$, 5-BS-A

Fig. 4.15 General view at second peak, $1\Delta_1$, 5-BS-A

Fig. 4.16 General view after 3 cycles, 5-BS-A

As cycling at higher deformations continued, the concrete cover at the column compression zones progressively deteriorated. Figure 4.17 is a photograph of the specimen after the loose concrete had been removed upon completion of the test. Notice that the deterioration of the column was greater at the bottom of the joint than at the top. Another interesting observation was that the cracks that formed at the beam-column boundaries varied in width from one side of the beam to the other. It was not apparent whether the cracks were a result of column or beam rotation, but the varying width indicated that the cracks were formed at least partially by column rotation.

4.4 Comparison of Monotonic and Cyclic Tests

4.4.1 General. A decline in joint performance due to cycling of deformations can be shown by comparing the plots of joint rotation versus interstory displacement for the cyclic and monotonic tests (see Fig. 4.18). At equivalent deflections, the cyclically loaded specimen had higher joint rotation than the monotonically loaded specimen. At $3\Delta_1$, the joint rotation for the cyclic test was 44 percent higher than that of the monotonic test. This indicates that cycling caused damage to the joint which resulted in higher joint rotation when the next deformation level was imposed.

4.4.2 Components of Beam Deflection. Several of the mechanisms which contributed to the total deformation of the specimens were either calculated or measured. The mechanisms were inelastic beam rotation, inelastic column rotation, joint shear strain, and elastic flexural deformation of both the column and beams. To appreciate the relative influence of the component deformations, beam-end deflection was selected as a common reference and deflections were calculated for each of the components. Figure 4.19 shows schematic representations of the various components. Notice

Fig. 4.17 Specimen 5-BS-A after testing

Fig. 4.18 Joint rotation versus interstory displacement (N-S direction)

Fig. 4.19 Components of beam deflection

that all of the mechanisms except beam rotation, contribute to the rotation of the joint.

Beam deflection due to beam and column elastic flexural deformation, Δ_E , was calculated as shown in Fig. 4.20. The gross moment of inertia of the column was used in the calculations, and based on the results of the elastic test, the moment of inertia of the beam was determined to be approximately $\frac{1}{4}$ the gross value. Figure 4.21 shows the geometry of the specimen due to joint shear strain and the calculation of the beam deflection due to joint shear strain, Δ_S , is given below.

$$\Delta_S = \varphi_2 L_b - \varphi_1 W_j / 2$$

where φ_2 = component of joint rotation due to joint shear strain, rad.

Note: $\Delta_1 = \varphi_1 L_c = \varphi_2 h_j / 2 \Rightarrow \varphi_1 = \frac{\varphi_2 h_j}{2L_c}$

α = joint shear strain, rad.

$$= \varphi_1 + \varphi_2$$

$$= \frac{\varphi_2 h_j}{2L_c} + \varphi_2$$

Therefore,

$$\varphi_2 = \frac{\alpha L_c}{L_c + h_j / 2}$$

From above,

$$\varphi_1 = \varphi_2 \frac{h_j}{2L_c}$$

$$\theta_f = \left(\frac{M_1 + M_2}{2} \right) \frac{1}{EI_c} (l_c) \left(\frac{1}{2} \right) \frac{2}{3}$$

$$\Delta_E = \theta_f (l_b + W_j/2) + \frac{M_3}{3EI_B} l_b^2$$

$$E = 57000 \sqrt{E_c} \approx 3800 \text{ ksi}$$

$$I_c = \frac{bh^2}{12} = \frac{15^4}{12} = 4220 \text{ in.}^4$$

$$I_B \approx \frac{1}{4} \frac{bh^3}{12} \approx 1500 \text{ in.}^4 \text{ (based on test results)}$$

$$l_c = 63 \text{ in.}$$

$$l_b = 54 \text{ in.}$$

$$W_j = 15 \text{ in.}$$

$$\therefore \Delta_E = (1.31 \times 10^{-6}) \left(\frac{M_1 + M_2}{2} \right) + (1.71 \times 10^{-4}) M_3$$

Fig. 4.20 Calculation of elastic flexural deformation

Fig. 4.21 Joint shear strain geometry

$$\begin{aligned}\varphi_1 &= \left(\frac{\alpha L_c}{L_c + h_j/2} \right) \frac{h_j}{2L_c} \\ &= \frac{\alpha h_j}{2L_c + h_j} \\ \Delta_S &= \left(\frac{\alpha L_c}{L_c + h_j/2} \right) L_b - \left(\frac{\alpha h_j}{2L_c + h_j} \right) \frac{W_j}{2}\end{aligned}$$

For this geometry, $L_c = 63$ in., $L_b = 60.5$ in., $h_j = 18$ in.,
 $W_j = 15$ in.

Therefore,

$$\Delta_S = 52 \alpha, \text{ in.}$$

Beam deflection due to beam inelastic rotation, Δ_B , was simply the beam rotation multiplied by the length of the beam. This component also includes the flexural rotation of the beam between the column face and the bracket from which the beam rotation was measured. The fourth component of beam deflection was due to the inelastic rotation of the column, Δ_c . This component was calculated by subtracting the other components from the measured total beam deflection.

$$\Delta_c = \Delta_{\text{total}} - \Delta_E - \Delta_S - \Delta_B$$

Ratios of the components of beam deflection were calculated using the total beam deflection as the base. Comparisons of the monotonic and cyclic tests are shown in Figs. 4.22 through 4.25 which show the component ratios plotted against the total beam deflection. Figure 4.22 shows that the ratio of elastic flexural deformation decreased as the total deformation increased. At high beam deflections, the inelastic mechanisms contributed a greater percentage of the total deflection and the percentage of elastic

Fig. 4.22 Ratio of elastic flexural deformation

Fig. 4.23 Ratio of joint shear deformation

Fig. 4.24 Ratio of inelastic column deformation

Fig. 4.25 Ratio of inelastic beam deformation

flexural deformation was not significantly different for the two tests. Figure 4.23 is a plot of the ratio of beam deflection due to joint shear strain and shows that joint shear strain contributed a significant portion of the total beam deflection. Thus, joint shear strain had a significant influence on the stiffness of the specimens. However, there was not a significant difference in the amount of joint shear strain between the monotonically and cyclically tested specimens. The ratio of beam deflection due to inelastic column rotation is shown in Fig. 4.24. There was a substantial difference in the amount of inelastic column rotation between the two tests. The cyclically loaded column had much larger inelastic rotations which may have occurred as a result of bond degradation of the reinforcement in the joint region. Beam inelastic rotation, on the other hand, was higher for the monotonically tested specimen as shown in the plot of the ratio of beam deflection due to beam inelastic rotation (see Fig. 4.25). The absence of cycling of deformations resulted in better joint performance for the monotonically tested specimen, and the imposed beam deflections resulted in larger beam rotations.

4.4.3 Bar Slip Measurements. Slip of top and bottom beam bar reinforcement was measured at the critical sections of the beam. A characteristic of all the bar slip measurements was the slip of the bar away from the face of the column as the beams were cycled at larger deformation levels (see Figs. 4.26 and 4.27). Tensile yielding and the subsequent elongation of the bars caused progressive slip of the reinforcing bars away from the column face. The amount of slip toward the joint was not great enough for the bars to return to their original neutral position.

The compression zones of the column may have had an effect on the magnitude of bar slip toward the joint (negative slip). Since the specimens were loaded on a 45° diagonal, the compression zones of the column were located at the northwest and southeast corners

Fig. 4.26 North beam deflection versus #8 top bar slip

Fig. 4.27 West beam deflection versus #6 bottom bar slip

of the column, and the northeast and southwest corners were near the neutral axis. The bars at the northwest and southeast corners of the column had lower negative slip than measured at the northeast and southwest corners. Figures 4.28 and 4.29 are plots of beam load versus bar slip measured at the southwest and southeast corners, respectively. In Fig. 4.28, one can see that slip is greater in the negative direction, but less in the positive direction than the slip for the bar in the southeast corner (Fig. 4.29). The column compressive zone in the southeast corner may have had an influence in reducing the negative slip of the top bar in that corner.

The magnitude of the bar slips ranged from about 0.05 in. at the small deformation level to about 0.30 in. at the largest deformation level and varied approximately linearly with beam deflection. The effect of cycling was to shift the neutral position of the bar away from the face of the column due to inelastic elongation of the bar with each cycle. Considering this shift, the magnitudes of slip with respect to the neutral position were not significantly different for the monotonic and cyclic tests. Bar slip depended on beam end deflection and the total amount of inelastic bar strain.

Even though cycling had little influence on the magnitude of bar slip, it should be recognized that frictional resistance between the concrete and bar and the bearing force of the bar deformations against the concrete are greatly reduced after the initial excursion to a given deformation. This had a significant effect on the stiffness of the joint for the second and third cycles at the given deformation.

4.4.4 Bar Stresses and Strains. Strains were measured in the beam and column longitudinal bars and in the joint hoops at the location shown in Fig. 3.18. Because of high joint shear

Fig. 4.28 South beam deflection versus #8 top bar slip

Fig. 4.29 East beam deflection versus #8 top bar slip (5-BS-A)

distortion and beam inelastic rotation, considerable bending of the bars occurred at the beam-column boundaries. As a result, the strains measured at the beam-column boundaries included bending strains as well as axial strains. However, strain measurements taken at 8 in. and 16 in. away from the beam-column boundaries did not appear influenced by bar bending. Therefore, only the strain measurements of the longitudinal beam and column bars away from the beam-column boundaries were considered.

Reinforcing bar stresses were calculated using Program STRESS (see Appendix) which is based on Thompson's method for calculating steel stresses for cyclically loaded bars in the inelastic range.⁷ A modification of Thompson's method was necessary so that the stress after strain hardening was not underestimated. The yield stress in the equation for calculating characteristic stress was replaced by the maximum stress reached for that loading direction prior to the half cycle under consideration. In other words, if the stress was greater than yield, then that stress was assumed to be the new yield stress for subsequent calculations. It should also be noted that the equations were used in their original form and were calibrated using data from cyclic tests on reinforcing bars performed at the University of Canterbury. For qualitative purposes, the original calibration was assumed to be adequate.

Beam Bars. The stresses of an instrumented #8 top bar of the east beam are shown in plots of bar stress versus beam deflection (see Figs. 4.30 and 4.31). The east beam was first loaded in the negative direction (up), which would normally cause the top bars to go into compression. The plots, however, show that tensile stresses were produced in the top bars of both the monotonically and cyclically loaded specimens even though the compression zone was at the top. Analysis of the east beam cross section indicated

Fig. 4.31 #8 top bar stress versus east beam deflection
(16 in. from joint boundary)

that at the ultimate load, the neutral axis was above the compression reinforcement putting the top bars in about 20 ksi tension. The tensile stress of the top bar of the cyclically loaded specimen, however, was approaching 40 ksi at the extreme deformation. This indicates that a portion of the tensile stress in the bar occurred because of bond degradation through the joint (see Fig. 4.13).

Plots of beam load versus #6 bottom bar strain (Figs. 4.32 and 4.33) show that inelastic strains occurred as far away as 8 in. from the joint, but remained elastic at 16 in. away. The inelastic elongation of the #6 bottom bars was concentrated closer to the critical section than the larger top bars which had inelastic strains at 16 in. into the beams. These observations indicate that the bond condition was more favorable for the #6 bars than the #8 bars. Also, the monotonically loaded specimen had larger bar strains than the cyclically loaded specimen which indicates a less favorable bond condition for the cyclically loaded specimen.

Column Bars. Since the columns were loaded on the northwest-southeast diagonal, the extreme fibers were located at the northwest and southeast corners of the column. Strain measurements of the southeast column bar which had gages at 8 in. and 16 in. above and below the joint remained in the elastic range indicating that the column capacity was governed by a compressive rather than a tensile failure. Plots of the southeast column bar stress versus interstory displacement (Figs. 4.34 and 4.35) show that the compressive bar stress of specimen 5-BS-A was higher at 8 in. below the joint compared to the compressive bar stress of specimen 6-MBS-A. At 16 in. below the joint, however, the compressive stress of specimen 6-MBS-A was higher. Indications are that cycling of deformations caused the deterioration of the concrete near the joint and resulted in higher stresses in the reinforcement. The tensile stresses of the same column bar were about the same at both

Fig. 4.32 East beam load versus #6 bottom bar strain (8 in. from joint boundary)

Fig. 4.33 East beam load versus #6 bottom bar strain
(16 in. from joint boundary)

Fig. 4.34 Southeast column bar stress versus interstory displacement (8 in. below joint boundary)

Fig. 4.35 Southeast column bar stress versus interstory displacement (16 in. below joint boundary)

8 in. and 16 in. below the joint of the cyclically loaded specimen indicating that the bond deterioration of the column bars occurred well below the joint boundary. Greater bond deterioration of the cyclically loaded specimen may be the reason for the high inelastic column rotations observed for that specimen.

Joint Hoops. Joint hoops of both the monotonically and cyclically loaded specimens had tensile strains well above yield as shown in the plots of stress versus strain in Figs. 4.36 and 4.37. Each specimen had two joint hoops as shown in Fig. 3.4. At the lower deformations, the top joint hoop of the cyclically loaded specimen consistently had higher strains than the bottom joint hoop. The different sizes of the top and bottom reinforcement may have been an influencing factor for this behavior. At the larger deformations, however, the trend broke down as larger strains were reached. The magnitude of the strains varied considerably at the larger deformations. The monotonically loaded specimen had hoop strains that ranged from 0.00213 to 0.0215 at $3\Delta_i$ (load stage 26). The cyclically loaded specimen also had a wide range of hoop strains that varied from 0.002571 to 0.0178 at $3\Delta_i$ (load stage 125). Joint shear cracks crossing the hoops at the position of the strain gage may have resulted in large strains at those points.

Plots of hoop stress versus interstory displacement of the cyclically loaded specimen are shown in Figs. 4.38 and 4.39. During the early cycles, tensile stresses of the joint hoops remained locked in when the specimen was returned to the original position. Cracks which opened in the joint region may not have closed completely because of concrete particles which could have lodged in the open cracks. However, as cycling progressed, the amount of locked-in stress decreased, and eventually compressive stresses were achieved. This may have happened because as cracks grew

Fig. 4.36 Top joint hoop stress versus strain (6-MBS-A)

Fig. 4.37 Top joint hoop stress versus strain (5-BS-A)

Fig. 4.38 Top joint hoop stress versus interstory displacement (5-BS-A)

Fig. 4.39 Bottom joint hoop stress versus interstory displacement (5-BS-A)

larger and greater in number, inelastic elongation of the hoops occurred, and when the load was reversed, the cracks closed and compressive stresses were produced. Generally, the joint hoops of both the monotonically and cyclically loaded specimens underwent large inelastic strains indicating that the joints were under considerable distress.

CHAPTER 5

COMPARISON OF EXPERIMENTAL AND CALCULATED JOINT SHEAR STRENGTH

5.1 General

Joint shear was calculated using internal moment arms, d_1 and d_2 as shown in Fig. 5.1. The values of d were selected based on calculations of the internal moment arms in the elastic range and at ultimate. The average value of d at the two conditions was chosen to be used in the calculations. The values of d varied because of the different levels of the reinforcement in the N-S and E-W beams and because of the different amounts of positive and negative reinforcement. Considerable spalling of the cover concrete occurred at the higher levels of deformation, and it is likely that the actual values of d were less than those indicated in the figure. If so, the joint shear would be greater than that calculated. Joint shear was calculated using constant internal moment arms throughout the tests, so at the higher deformations where spalling occurred, the values of joint shear are probably conservative. Figures 5.2 and 5.3 are plots of joint shear versus interstory displacement and Table 5.1 lists the values of joint shear at various load stages. The maximum joint shear was approximately 225 kips in each of the principal directions for both tests 5-BS-A and 6-MBS-A. Thus, the component of nominal joint shear stress in each direction is calculated as follows:

$$\begin{aligned}v_u &= \frac{V_u}{bd} = \frac{225,000 \text{ lbs.}}{(15 \text{ in.})(12.4 \text{ in.})} \\ &= 1210 \text{ psi} \\ &= 18.3 \sqrt{f'_c}\end{aligned}$$

$$\begin{aligned} \text{Joint Shear} &= T_1 + C_2 - V_{col} \\ &= P_1 l / d_1 + P_2 l / d_2 - V_{col} \end{aligned}$$

In this section, the joint shear strength of the test specimen will be calculated using several design approaches based on previous studies of planar joints. Comparisons of the maximum applied joint shears with the calculated values should give some insight as to the relative magnitude of the joint shear strength of biaxially loaded joints as well as to the validity of the various design approaches. The design approaches which will be considered were developed by ACI-ASCE Committee 352,⁵ Park and Paulay at the University of Canterbury,⁸ Sugano and Koreishi at the University of Tokyo,⁹ and Meinheit and Jirsa at The University of Texas at Austin.⁶

5.2 ACI-ASCE Committee 352^{5,6}

The ACI ASCE Committee 352 design procedure divides the joint shear strength into two components; one portion is attributed to the concrete and the other to the joint reinforcement. This method is based on the classical truss analogy which is also the basis for the shear design of reinforced concrete beams. The allowable unit stress carried by the concrete is calculated with the following equation.

$$v_c = 3.5\beta\gamma \left[f'_c (1 + 0.002N_u/A_g) \right]^{-1/2}$$

where β = factor reflecting the amount of energy absorbing capacity or type of loading imposed on the structure

- = 1.4 for joints which must have strength but no expected significant inelastic deformations (Type 1)
- = 1.0 for joints which must have sustained strength under load reversals in the inelastic range (Type 2)

γ = factor reflecting lateral confinement by members perpendicular to the plane in which the shear stress is calculated

$\gamma = 1.4$ if the confining members cover at least three-quarters of the width and three-quarters of the depth of the joint face.

= 1.0 if the confining members do not meet the above requirements

f'_c = concrete compressive strength, psi

N_u = magnitude of column load (compressive positive), lbs.

A_g = gross area of column, in²

The unit stress carried by the steel reinforcement is calculated as follows:

$$v_s = A_{sv} f_y / bs$$

where A_{sv} = area of reinforcement crossing a shear crack within a distance s , in²

f_y = yield strength of reinforcement, psi

b = width of the column in the joint, in.

s = spacing of reinforcement, in.

The ultimate shear stress is the addition of the two components:

$$v_u = v_c + v_s$$

For the test specimens,

$$\beta = 1.4$$

$$\gamma = 1.4$$

$$f'_c = 4350 \text{ psi}$$

$$N_u = 300,000 \text{ lbs.}$$

$$A_g = (15)(15) = 225 \text{ in}^2$$

$$v_c = 3.5(1.4)(1.4) \left[4350 \left(1 + 0.002 \frac{300,000}{225} \right) \right]^{\frac{1}{2}}$$

$$= 866 \text{ psi}$$

$$V_c = v_c b d = 866(15)(12.4) = 162,000 \text{ lbs.}$$

$$A_{sv} = 0.40 \text{ in}^2$$

$$f_y = 63,800 \text{ psi}$$

$$b = 15 \text{ in.}$$

$$s = 5 \text{ in.}$$

$$v_s = \frac{0.40(63,800)}{(15)(5)} = 340 \text{ psi}$$

$$V_s = v_s b d = 340 (15)(12.4) = 63,000 \text{ lbs.}$$

$$V_u = V_c + V_s = 162 + 63$$

$$= 225 \text{ kips}$$

When inelastic load reversals are expected, $\beta = 1.0$ instead of 1.4. Therefore, the sustained shear strength is calculated as follows:

$$v_c = 866/1.4 = 619 \text{ psi}$$

$$v_{\text{sustained}} = 619 + 340 = 959 \text{ psi}$$

$$V_{\text{sustained}} = 959(15)(12.4) = 178,000 \text{ lbs.}$$

5.3 Park and Paulay⁸

The design approach suggested by Park and Paulay attributes none of the shear strength to the concrete when load reversals in the inelastic range are anticipated. This approach assumes the concrete will degrade under seismic loading conditions and will have little or no shear strength. Also, cracks that form at the joint boundaries may remain open due to inelastic elongation and the concrete will become ineffective in transferring the shear through the joint. The steel reinforcement must then be capable

of transferring the shear through the joint by means of the "truss" mechanism. If the loadings are skewed with respect to the principal axes of the frame, the joint core must resist the forces from four beams simultaneously. The shear in the joint core is increased by $\sqrt{2}$ above that of the uniaxial case if the beams are similar in each direction. Also, the steel reinforcement will cross the diagonal cracking pattern at a 45 degree angle and will be $1/\sqrt{2}$ times as effective. Hence, if resistance is by the "truss" mechanism alone, twice the amount of steel will be required for biaxial design.¹⁰

The joint shear strength will be equal to the portion attributed to the steel reinforcement in the ASCE-ACI Committee 352 method.

$$v_u = v_s = 340 \text{ psi}$$

$$V_u = v_u bd = 340 (15)(12.4) = 63,200 \text{ lbs.}$$

5.4 Sugano and Koreishi⁹

The Sugano and Koreishi design approach is similar to the ACI-ASCE Committee 352 recommendation in that the shear resistance is divided into two components. The shear resistance assigned to the steel reinforcement and to the concrete are calculated separately and then combined to obtain the total joint shear strength. Equations for calculating cracking strength were also included in their recommendations and are given below.

$$v_{cr} = (f_t^2 + f_t(P_u/A_g))^{1/2}$$

where f_t = tensile strength of concrete, kg/cm^2

P_u = column load, kg

A_g = gross area of column, cm^2

and $f_t = 0.205f'_c - 0.0004f'^2_c$ ($f'_c \leq 420\text{kg/cm}^2$)

where f'_c = concrete compressive strength, kg/cm^2

For the test specimens:

$$f'_c = 4350 \text{ psi} = 305 \text{ kg/cm}^2$$

$$P_u/A_g = \frac{300,000 \text{ lb.}}{(15 \text{ in.})(15 \text{ in.})} = 1330 \text{ psi} = 93.7 \text{ kg/cm}^2$$

$$\begin{aligned} f_t &= 0.205(305) - 0.0004(305)^2 \\ &= 25.3 \text{ kg/cm}^2 \end{aligned}$$

$$\begin{aligned} v_{cr} &= (25.3^2 + 25.3(93.7))^{\frac{1}{2}} \\ &= 54.9 \text{ kg/cm}^2 \end{aligned}$$

$$= 781 \text{ psi}$$

$$V_{cr} = v_{cr} bd$$

$$= 781(15)(12.4)$$

$$= 145 \text{ kips}$$

The concrete contribution to the ultimate shear strength is given by the following equation:

$$v_c = 0.51f'_c - 0.001f'^2_c \quad (f'_c \leq 420\text{kg/cm}^2)$$

And the shear strength provided by the steel reinforcement is calculated as follows:

$$v_s = 2.7(\rho_w f_y)^{\frac{1}{2}}$$

where ρ_w = the steel ratio (A_s/bs)

A_s = total area of hoop reinforcement in the joint

f_y = yield strength of joint hoops, kg/cm^2

b = width of column

s = spacing of hoops

$$\begin{aligned} v_c &= 0.51(305) - 0.001(305)^2 \\ &= 62.3 \text{ kg/cm}^2 \\ &= 893 \text{ psi} \end{aligned}$$

$$V_c = v_c(b)(d) = 893(15)(12.4) = 35,000 \text{ lbs.}$$

$$\begin{aligned} \rho_w &= 0.40/(15)(15) \\ &= 0.00533 \end{aligned}$$

$$\begin{aligned} f_y &= 63,800 \text{ psi} \\ &= 4485 \text{ kg/cm}^2 \end{aligned}$$

$$\begin{aligned} v_s &= 2.7 \left[0.00533(4485) \right]^{-\frac{1}{2}} \\ &= 13.2 \text{ kg/cm}^2 \\ &= 188 \text{ psi} \end{aligned}$$

$$V_s = 188(15)(12.4) = 166,000 \text{ lbs.}$$

$$\begin{aligned} V_u &= V_c + V_s \\ &= 35 + 166 \\ &= 201 \text{ kips} \end{aligned}$$

5.5 Meinheit and Jirsa⁶

The design approach recommended by Meinheit and Jirsa does not divide the shear resistance due to the concrete and the steel reinforcement into separate components. The shear strength of the joint is assigned primarily to the concrete and any increase in

strength provided by the reinforcement is due to the confinement of the concrete. Confinement provided by lateral beams is also considered to improve the joint shear strength. The equations proposed by Meinheit and Jirsa for the ultimate joint shear strength were used previously in the design of the test specimens and are described in Chapter 2. In addition to the ultimate strength formula, an equation was given for the cracking strength which is calculated below:

$$\begin{aligned} v_{cr} &= 0.0124(f'_c)^{0.85} (P/A_g)^{0.485} (1 + w_c/h_c)^{0.57} \\ &= 0.0124(4350)^{0.85} \left(\frac{300,000}{15^2}\right)^{0.485} \left(1 + \frac{13}{15}\right)^{0.57} \\ &= 718 \text{ psi} \end{aligned}$$

$$\begin{aligned} V_{cr} &= v_{cr} bd \\ &= 718(15)(12.4) \\ &= 134,000 \text{ lbs.} \end{aligned}$$

Calculations of ultimate joint shear strength follows.

From Chapter 2,

$$\rho_s = 0.0133$$

$$\zeta = 1.08$$

$$\beta = 1.22$$

$$\begin{aligned} v_u &= 5.1\beta \zeta (f'_c)^{2/3} \\ &= 5.1(1.22)(1.08)(4350)^{2/3} \\ &= 1790 \text{ psi} \end{aligned}$$

$$\begin{aligned}V_u &= v_u bd \\ &= 1790(15)(12.4) \\ &= 333,000 \text{ lbs.}\end{aligned}$$

For joints designed for load reversals producing inelastic deformations, Meinheit and Jirsa recommend a reduction factor of 0.6 to obtain the sustained shear strength:

$$\begin{aligned}V_{\text{sustained}} &= 0.6(333,000) \\ &= 200,000 \text{ lbs.}\end{aligned}$$

5.6 Cracking Shear Strength

The results of the calculations of cracking shear strength obtained with equations by Sugano and Koreishi and Meinheit and Jirsa were compared with the experimental cracking strengths listed in Table 5.2. In each direction, the component shear on the joint core at cracking was about the same as predicted by the cracking equations which were based on studies of uniaxially loaded planar joints. These results indicate that the joint cracking strength is not adversely affected in one direction by loadings in the orthogonal direction. It appears that the initial cracking of a biaxially loaded joint occurs when the shear in either principal direction reaches the "uniaxial" cracking strength. Although the experimental values of the N-S and the E-W components of joint shear were close to the calculated values, the resultant joint shear on the specimens was about $\sqrt{2}$ times the calculated cracking strengths. The confining effect of the compression zones of the orthogonal beams may have improved the cracking strength of the joint.

5.7 Ultimate Shear Strength

The calculated ultimate joint shear strength and the maximum joint shear that was applied to the specimens is compared in Table 5.3. It should be noted that the maximum applied joint shear may have been less than the potential ultimate joint shear strength of the specimens because the applied joint shear was limited by the flexural capacity of the beams. The maximum joint shear applied to the specimens was exactly the same as the joint shear strength predicted by the ASCE-ACI design equations. It is probably coincidental that when the beams reached their flexural capacity, the joint shear on the specimen was the same as the calculated shear strength. While it cannot be concluded that the ASCE-ACI design approach accurately models joint behavior, it is reassuring that the ASCE-ACI method gives values of joint shear strength that are in the correct range for biaxially loaded joints.

It is reasonable to assume that the N-S and E-W components of joint shear capacity would be less for a biaxially loaded beam-column joint than the joint shear capacity of the same joint loaded uniaxially. If the ultimate shear capacity of a joint is the same regardless of the direction of the resultant shear, then the N-S and E-W components of the ultimate joint shear strength of a joint loaded equally in each direction will be $1/\sqrt{2}$ or 0.71 times the "uniaxial" strength. Two of the design approaches, however, predicted that the "uniaxial" joint shear strength would be less than each component of the joint shear that was actually applied to the specimens. Park and Paulay's design approach underestimated the joint shear strength by 72 percent. It should be obvious from this comparison that the joint shear strength contributed by the concrete should not be totally neglected. Sugano and Koreishi's design approach attributed 83 percent of the joint shear strength to the concrete, but also underestimated the capacity by 11 percent. However, both the N-S and E-W components of applied joint

shear were 0.68 times the "uniaxial" joint shear strength predicted by Meinheit and Jirsa's method. This is very close to 0.71 which is the ratio that would be expected if the joint shear capacity is independent of the orientation of the applied shear.

Depending on the design approach which is considered, different conclusions about the relative strength of biaxially loaded joints may be drawn from the comparisons of calculated ultimate and applied joint shear. Park and Paulay's design approach, which considers only the joint shear strength contribution by the steel, did not accurately predict the joint shear strength of the specimens, so no meaningful conclusions could be made. Sugano and Koreishi's equations gave values of joint shear strength which were fairly close to the N-S and E-W components of the maximum joint shear applied to the specimens. This indicates that biaxial shear on the specimens did not decrease the joint shear capacity in either the N-S or E-W directions, so the resultant joint shear strength was improved by the biaxial loads. The joint shear strength predicted by Meinheit and Jirsa's equations, however, was higher than the maximum applied joint shear. Contrary to the conclusions drawn from the results of Sugano's and Koreishi's method, this indicates that the joint shear strength in the principle directions may be less for biaxial loadings than for uniaxial loadings. If so, the resultant shear strength of the joint may be the same as predicted by the "uniaxial" equations.

These results indicate that all of the design approaches considered, except for Meinheit and Jirsa's are conservative and can be used in their present form to design joints for biaxial loads. The "uniaxial" joint shear strength calculated with Meinheit and Jirsa's method may be unconservative if bidirectional loads are present. Therefore, the calculated joint shear strength

should be multiplied by approximately $1/\sqrt{2}$ to obtain the strength in each direction when biaxial loads are expected. These conclusions are valid for the two specimens being considered and may not be true for joints with different geometry or reinforcing details.

After six cycles into the inelastic range, Specimen 5-BS-A continued to carry high joint shear. At the first peak of the $3\Delta_1$ deformation (load stage 137), the N-S and E-W components of joint shear were 185 and 174 kips, respectively. This is a 20 percent reduction from the maximum applied joint shear. The decay in strength probably resulted from a combination of factors including loss of cover concrete in the beams and column, loss of strain compatibility between the compression reinforcement and the concrete, and decay of the concrete strength in the joint region. Considering the severe load history that was applied, the strength decay was small.

5.8 Concluding Remarks

The different design approaches yielded conflicting conclusions about the strength of biaxially loaded joints relative to the strength of uniaxially loaded joints. The difficulty is made even greater because so little test data are available. But to further explore the implications of the comparisons, it is necessary to select the design method which is believed to best represent the actual joint behavior of the specimens. The specimens being considered in this paper were similar in geometry and reinforcement details to the specimens which Meinheit and Jirsa used in their test program; therefore, it is logical that their method should give a more meaningful comparison. Comparison of the test results with the calculated results of Meinheit and Jirsa's method indicated that resultant joint shear strength may be independent of the orientation of the applied shear and may be the

the same as the "uniaxial" joint shear strength predicted by the design equations. For practical design, it may be necessary to proportion a joint to carry a resultant shear of approximately $\sqrt{2}$ or 1.4 times the shear capacity necessary in each principal direction. For joints with unequal size beams framing into the column from orthogonal directions, a smaller factor may be adequate. This approach to the design for biaxial loads is a consideration which should be explored in greater detail as additional test results become available.

CHAPTER 6

SUMMARY AND CONCLUSIONS

6.1 Summary

The objectives of this study were to compare the behavior of monotonically and cyclically loaded beam-column joints under biaxial loadings and to compare their behavior with design approaches based on uniaxial tests.

Two reinforced concrete beam-column joints with the same geometry and reinforcing details were tested under bidirectional loads. The specimens were designed to exhibit joint distress while avoiding large inelastic rotations of the column and were tested with deformation controlled load histories. The applied joint shear on both of the specimens was limited by the flexural capacity of the beams. Specimen 6-MBS-A showed no sign of a joint shear failure during the monotonic loading. Specimen 5-BS-A, which was cyclically tested, also showed no clear sign of a joint shear failure, although at the $3\Delta_1$ deformation, the capacity of the specimen did decrease by 20 percent. The stiffness of the specimens decreased considerably after the first excursion to a new deformation level and severe pinching of the hysteresis loops was evidence that the stiffness was influenced largely by joint shear strain and reinforcing bar slip through the joint.

The major difference between the two tests was the amount of inelastic rotation of the beam and columns. As the beam deformations were increased, the percentage of the total deformation due to inelastic column rotation increased for the cycled specimen, but remained constant during the monotonic loading. The opposite trend was true for the beam rotations. Loss of

compatibility of the column reinforcement caused by cycling was probably the key factor for this behavior. Surprisingly, the amount of joint shear distortion was not affected by cycling of deformations.

In Chapter 5, the applied joint shear on the specimens was compared with the calculated strengths using several design approaches which were based on studies of uniaxially loaded joints. The cracking shear strengths of the joints were about the same in each of the principal directions as predicted by the cracking equations by Sugano and Koreishi and Meinheit and Jirsa. The ultimate joint shear strength of the specimens was calculated with several design equations, and large variations were obtained. Based on a comparison of the observed joint shear strength with the calculated joint shear strength using Meinheit and Jirsa's method, it appears that the ultimate joint shear strength is independent of the orientation of the applied joint shear, and that biaxial loadings may reduce the strength in the principal directions. Considering this behavior, it may be necessary to proportion joints to resist greater shears in each direction if the "uniaxial" design approaches are adopted.

6.2 Conclusions

The following conclusions regarding the behavior of biaxially loaded beam-column joints are based on the test results of two specimens and may not be valid for joints with different geometry or reinforcing details.

(a) Conclusions Regarding Joint Behavior

- (1) Joint shear strength was high enough to develop the flexural strength of the beams and deteriorated little with cycling.

- (2) Joint stiffness depended on the level of deformation imposed and was influenced substantially by bar slip and joint shear strain.
- (3) Cycling of deformations had a large influence on the deterioration of the column.

(b) Conclusions Regarding Design Approaches

- (1) Based on a comparison of the joint shear cracking strength of the specimens with the "uniaxial" cracking strengths calculated with equations by Sugano and Koreishi and Meinheit and Jirsa, it appears that initial cracking of the joint does not occur until the "uniaxial" cracking strength in either direction is reached.
- (2) The joint shear strength calculated with the design equations by the ACI-ASCE Committee 352 and by Sugano and Koreishi were close to the N-S and E-W components of the maximum applied joint shear.
- (3) The design method by Park and Paulay, which neglects the strength of the concrete, grossly underestimated the ultimate joint shear strength of the specimens.
- (4) Based on a comparison of the maximum applied joint shear and the ultimate joint shear strength calculated with Meinheit and Jirsa's method, it appears that the joint shear strength in one direction may be reduced by loading in the orthogonal direction. If this design approach is used, it may be necessary to proportion joints to carry a higher joint shear in each direction to account for the effects of bidirectional loads.

6.3 Concluding Remarks

It is difficult to make general conclusions regarding the effects of biaxial loadings on beam-column joints from the test results of two specimens. This study, however, marks the beginning of an ongoing endeavor to understand and quantify the behavior of joints subjected to bidirectional loads.

PROGRAM STRESS

STRESS is a Fortran program which calculates the stress history of mild steel reinforcing bars which have strain histories in the inelastic range. The basis for the program is the method developed by K. J. Thompson at the University of Canterbury.⁷ Included in this appendix are the equations which were used, an input guide, a listing of the program, and sample output.

The monotonic loading envelope is calculated according to the following rules:

$$\begin{aligned} \text{If } \epsilon_s &\leq \epsilon_{sy}, & f_s &= E_s \epsilon_s \\ \text{if } \epsilon_{sy} &\leq \epsilon_s \leq \epsilon_{sh}, & f_s &= f_{sy} \\ \text{if } \epsilon_{sh} &< \epsilon_s \leq \epsilon_{su}, & f_s &= f_{sy} \left(\frac{Q(\epsilon_s - \epsilon_{sh}) + 2}{60(\epsilon_s - \epsilon_{sh}) + 2} + \frac{(\epsilon_s - \epsilon_{sh})(60 - Q)}{2(30q + 1)^2} \right) \end{aligned}$$

where f_s = stress value on analytical curve

f_{sy} = yield stress

f_{su} = ultimate stress

E_s = Young's modulus

ϵ_s = strain value on analytical curve

ϵ_{sy} = yield strain

ϵ_{sh} = strain at strain hardening

ϵ_{su} = ultimate strain

$$Q = \frac{\frac{f_{su}}{f_{sy}} (30q + 1)^2 - 60q - 1}{15q^2}$$

and $q = \epsilon_{su} - \epsilon_{sh}$

The equations for cyclic loading are given below:

$$E_s(\epsilon_s - \epsilon_o) = (f_s - f_o) \left[1 + \left| \frac{f_s - f_o}{f_{ch} - f_o} \right|^{r-1} \right]$$

where ϵ_o = strain value at beginning of analytical curve

f_o = stress value at beginning of analytical curve

f_{ch} = characteristic stress

$$= f_{\max} (0.973 - 9.806 \epsilon_{pl})$$

f_{\max} = maximum prior stress for that direction $\geq f_{sy}$

ϵ_{pl} = plastic strain imposed during previous cycle

$$r = 12.231 + \frac{45.071}{e^{1000 \epsilon_{pl}}} - \frac{9.771}{\log_e(1000 \epsilon_{pl} + 2)}$$

Interested persons should see Ref. 7 for more detail about the equations and the rules for their use.

Joe Eldon Longwell was born in Raymondville, Texas, on November 30, 1952, the son of Garnet Jeanette Longwell and Percy Eldin Longwell. After completing his work at Raymondville High School in 1971, he entered Sam Houston State University at Huntsville, Texas. After one year of college, he was drafted into the United States Army, and his term of service lasted from May 1972 to May 1974 and included a tour in West Germany. In January 1975, he entered the College of Engineering at The University of Texas at Austin and received a Bachelor of Science in Civil Engineering in May 1978. In June 1978 he entered The Graduate School of The University of Texas at Austin.
